Resource-Constrained Geometric Network Optimization

Esther M. Arkin* Joseph S. B. Mitchell† Giri Narasimhan‡

Abstract

We study a variety of geometric network optimization problems on a set of points, in which we are given a resource bound, B, on the total length of the network, and our objective is to maximize the number of points visited (or the total "value" of points visited). In particular, we resolve the well-publicized open problem on the approximability of the *rooted* "orienteering problem" for the case in which the sites are given as points in the plane and the network required is a cycle. We obtain a 2-approximation for this problem. We also obtain approximation algorithms for variants of this problem in which the network required is a tree (3-approximation) or a path (2-approximation). No prior approximation bounds were known for any of these problems.

We also obtain improved approximation algorithms for geometric instances of the unrooted orienteering problem, where we obtain a 2-approximation for both the cycle and tree versions of the problem on points in the plane, as well as a 5-approximation for the tree version in edge-weighted graphs. Further, we study generalizations of the basic orienteering problem, to the case of multiple roots, sites that are polygonal regions, etc., where we again give the first known approximation results.

Our methods are based on some new tools which may be of interest in their own right: (1) some new results on m-guillotine subdivisions in the plane, strengthening the original approximation bound, and (2) some new combinatorial results on partitioning trees.

Our study helps to highlight where geometry "helps" in being able to approximate these hard combinatorial optimization problems.

1 Introduction

Consider a traveling salesperson who has a given amount of gasoline (allowing travel up to distance B) and wants to maximize the number of sites visited before running out of gasoline. This problem is one of a class of *orienteering* problems that require us to design a network that visits a maximum number of nodes (sites), subject to an upper bound on the total length of the network.

In contrast with the classical traveling salesperson problem (TSP), which asks for a minimum-length cycle visiting *all* sites, in the orienteering problem there is a resource constraint on the length of the cycle and the problem is to do the "best possible" in the sense of maximizing the number of sites visited. In a sense, the orienteering problem is dual to the problem of minimizing the length of a cycle, subject to meeting a quota on the number of sites visited (in the "k-TSP" version) or the sum of the values of the sites visited (the "quota-driven salesperson" problem).

The orienteering problem has also been called the "bank robber" problem (a thief wishes to maximize the "haul", with a single tank of gas in the get-away car) and the "generalized traveling salesperson problem" [16, 30]. The name "orienteering" comes from the outdoor sport by the same name, in which each player is given a compass and a map of a given outdoor terrain, and has the goal to accumulate the largest score within a fixed amount of time. Players set out from a given root (the "home base"), and obtain a certain score (value) by visiting a subset of the n sites ("control points") before returning to the root.

In this paper, we distinguish between different versions of the orienteering problem according to the type of network that is to be constructed: In the *tree-orienteering* (*path-orienteering*, *cycle-orienteering*) problem, we must construct a tree (path, cycle, resp.) visiting a subset of a given set of n *sites*, subject to an upper bound B on the total length of the network. Additionally, we may have one or more *roots*, which are "essential" sites that we require the network to visit.

The *rooted* orienteering problem has, for several years, been a particularly challenging problem from the point of view of approximation algorithms — in fact, prior to our

work, *no* approximation algorithms have been known for the problem, either in graphs or in geometry. Here, we provide *constant*-factor approximation algorithms for the geometric instances of the problem, in which the sites are given as points in the plane.

Summary of Main Results:

1. We give a 2-approximation algorithm for the *rooted* cycle- and path-orienteering problems on a set of points in the plane. This result is the first of its kind, as no approximation algorithms were previously known.
2. We give a 3-approximation algorithm for the rooted tree-orienteering problem, for points in the plane. Again, no prior approximation algorithms were known.
3. We give improved approximation algorithms for the unrooted instances of the orienteering problem. These results include a 2-approximation for the geometric tree-, path-, and cycle-orienteering, and a 5-approximation for tree-orienteering in edge-weighted graphs.
4. We study the *multiply-rooted* versions of the orienteering problems in the plane, providing both an approximation algorithm when the number of roots is a constant, and a proof of hardness of approximability when the number of roots is part of the input.
5. We study geometric instances of the orienteering problems in which the sites are given as a set of *regions* (polygons) in the plane. We give $O(\log n)$-approximation algorithms for these versions.

Key to our methods are some new tools which may be of independent interest:

(1) We obtain new results on approximating an arbitrary connected planar subdivision with an m-guillotine subdivision, strengthening the original analysis given in Mitchell [23]; these new theorems seem to be crucial in addressing the types of approximation problems that arise in the rooted cases, and they may be more widely applicable.

(2) We obtain a variety of new combinatorial results on partitioning trees; these lemmas are critical in obtaining some of our improved bounds on the unrooted versions of the orienteering problems, as well as in analyzing the generalizations to non-point sites.

Related Work

There has been a wealth of work on the related traveling salesperson problem (TSP), both in networks and in geometric settings [9, 18, 29, 17]. TSP is NP-hard, even for points in the Euclidean plane. Until recently, the best approximation algorithm known for the Euclidean TSP was the Christofides heuristic (see, e.g., [18]), which yields a 1.5-approximation for the more general case of undirected networks whose edge lengths obey the triangle inequality. Polynomial-time approximation schemes (PTAS) for geometric (e.g., Euclidean) instances were discovered recently by Arora [4, 5] and by Mitchell [21, 23, 24]; most recently, Rao and Smith [27] give a deterministic PTAS with running time $O(n \log n)$ in any fixed dimension. The methods of [21, 23] employ "m-guillotine subdivisions" in the plane; this tool is also essential for some of our results, which are based on a strengthening of some of the analysis in [21, 23].

A related problem is the k-MST problem, in which we are given a graph on n vertices with nonnegative distances on the edges, and an integer $k \leq n$, and our goal is to find a tree of least total weight that spans some subset of k vertices. The problem is known to be NP-hard, both in general graphs and in the Euclidean plane [12, 28, 31]. The current best approximation algorithm for general edge-weighted graphs is a 3-approximation by Garg [14], which applies also to the "rooted" case (the tree is required to include a given node); this has been improved to a 2.5-approximation, by Arya and Ramesh [6], if the tree is not "rooted." The Euclidean k-MST now has a PTAS [4, 5, 21, 23], as does the k-TSP, which asks for a shortest cycle visiting some subset of k points. For the graph version of the k-TSP, with edge weights obeying triangle inequality, Garg's method yields a 3-approximation for both the rooted and unrooted version; the result of Arya and Ramesh [6] does not apply.

Another related problem is the *quota-driven salesperson* problem, in which each site has an associated integral value, w_i, and a salesperson has a given integer quota, R. The objective is to find a shortest possible cycle such that the sum of the values for the sites visited is at least R. By replicating each site (w_i times), a k-MST approximation algorithm also gives an approximation for this problem. In the *prize-collecting salesman* problem, as studied by Balas [8] (see also [10]), the setup is the same as in the quota-driven salesman problem, except that, in addition to "values" w_i, there are non-negative penalties associated with each site, and now the objective is to minimize the sum of the distances traveled *plus* the sum of the penalties on the points *not* visited, subject to satisfying the quota R. As discussed in [7], an approximation algorithm follows from concatenating a cycle obtained for the quota-driven salesman, with the 2-approximation cycle given by the algorithm of Goemans and Williamson [15] (which considers the effect of penalties, but does not use the quota constraint).

The class of problems we address in this paper is based on the *orienteering problem* (or *bank robber* problem). The problem is essentially the dual of the quota-driven salesman problem: Given an upper bound on distance, B, maximize the total value of all points visited, for a salesperson that departs from a given root site. Heuristics were provided (without approximation guarantees) by [16, 30]. Awerbuch et al. [7] give an approximation algorithm for the *unrooted* cycle case, based on approximations to the k-TSP. These previous bounds are discussed in more detail later, as we compare them to our own results. For the original (rooted) version of the problem, it has been an intriguing open problem to obtain *any* nontrivial approximation algorithm.

Our work is also related to problems in bicriteria path optimization, in which we are to minimize one measure of "length", subject to an upper bound on another notion of "length"; see [2, 3, 11, 25], as well as the surveys by Mitchell [20, 22].

Preliminaries

We assume that the input to our problems is given by a set of n points (*sites*) in the Euclidean plane. For the path and cycle cases, we also consider a discrete metric space (an edge-weighted graph whose weights obey the triangle inequality), while for the tree case, we consider graphs with general (nonnegative) edge weights. We use the terms "length" and "weight" interchangeably. We let $d(p, q)$ denote the distance between p and q.

We let $n(T)$ and $w(T)$ denote the number of sites visited by network T and the total weight of T, respectively.

We let $B > 0$ be the given resource bound; B is an upper

bound on the total length of the allowed network (tree, path, or cycle).

A *root* is a site that is required to be covered by the network.

Sites may have associated weights ("values"). Assuming these weights are integral, we can replicate point sites, and thereby reduce the problem to the unweighted case, in which our objective is to maximize the *number* of sites visited by the network. (This approach results in time bounds that are pseudopolynomial, in n and the sum of the weights.) Thus, we focus on the unweighted case in the remainder of this paper.

In this paper, all algorithms are *polynomial-time* approximation algorithms, whose worst-case complexity is polynomial in n. We omit the term "polynomial-time," as well as the actual time bounds, in our statements of results. A c-approximation algorithm for a maximization (resp., minimization) problem is one which guarantees that the solution obtained has an objective value that is at least OPT/c (resp., at most $c \cdot OPT$), where OPT is the optimal value of the objective function.

We will have use of the definition of an "m-guillotine subdivision" from [23]; roughly speaking, an "m-guillotine subdivision" is a polygonal subdivision with the property that there exists a line ("cut"), whose intersection with the subdivision edges consists of a small number ($O(m)$) of connected components, and the subdivisions on either side of the line are also m-guillotine. The upper bound on the number of connected components allows one to apply dynamic programming to optimize over m-guillotine subdivisions, as there is a succinct specification of how subproblems interact across a cut.

More precisely, we consider a polygonal subdivision ("planar straight-line graph") S that has n edges (and hence $O(n)$ vertices and facets). Let E denote the union of the edge segments of S, and let V denote the vertices of S. We can assume (without loss of generality) that S (E) is restricted to the unit square.

In the following definitions, we fix attention on a given *window*, W, which is simply a closed, axis-aligned rectangle, with W in the unit square. We let $\overline{W} \subseteq W$ denote the minimal bounding box (axis-aligned rectangle) containing the vertices $V \cap W$ within W. A horizontal or vertical line ℓ is a *cut* for E (with respect to W) if $\ell \cap int(W) \neq \emptyset$. The intersection, $\ell \cap (E \cap int(W))$, of a cut ℓ with $E \cap int(W)$ (the restriction of E to the window W) consists of a discrete (possibly empty) set of subsegments of ℓ. (Some of these "segments" may be single points, where ℓ crosses an edge.) The ξ endpoints of these subsegments are called the *endpoints along* ℓ (with respect to W) and are denoted by $p_1, \ldots, p_\xi$, in order along ℓ.

For a positive integer m, we define the *m-span*, $\sigma_m(\ell)$, of ℓ (with respect to W) as follows. If $\xi \leq 2(m-1)$, then $\sigma_m(\ell) = \emptyset$; otherwise, $\sigma_m(\ell)$ is defined to be the (possibly zero-length) line segment, $p_m p_{\xi-m+1}$, joining the mth endpoint, p_m, with the mth-from-the-last endpoints, $p_{\xi-m+1}$.

A (horizontal or vertical) cut ℓ is an *m-perfect cut with respect to W* if $\sigma_m(\ell) \subseteq E$. In particular, if $\xi \leq 2(m-1)$, then ℓ is trivially an m-perfect cut (since $\sigma_m(\ell) = \emptyset$). Similarly, if $\xi = 2m-1$, then ℓ is m-perfect (since $\sigma_m(\ell)$ is a single point). Otherwise, if ℓ is m-perfect, and $\xi \geq 2m$, then $\xi = 2m$.

Finally, we say that S is an *m-guillotine subdivision with respect to window W* if either (1) $V \cap int(W) = \emptyset$; or (2) there exists an m-perfect cut, ℓ, with respect to the minimal window, $\overline{W} \subseteq W$, such that S is m-guillotine with respect to windows $W \cap H^+$ *and* $W \cap H^-$, where H^+, H^- are the closed halfplanes induced by ℓ. We say that S is an *m-guillotine subdivision* if S is m-guillotine with respect to the unit square.

2 Rooted Orienteering Problems for Points in the Plane

We begin by considering the *rooted* case of the orienteering problems, in which one particular site, r, is given, and the tree/path/cycle is constrained to contain r.

The effect of having a root is considerable, as far as approximation algorithms are concerned. The difficulty stems from the fact that an optimal network may visit a huge number of sites that lie in a very small cluster at a distance from r that is nearly B, making it difficult to visit at least a constant fraction of these sites, unless the network is very efficient in its use of length.

In fact, no previous approximation algorithms, even with a logarithmic approximation factor, were known for rooted orienteering problems. Here, by exploiting geometric structure, and tightening some analysis of m-guillotine subdivision approximations, we are able to obtain constant-factor approximations.

2.1 Rooted Tree-Orienteering Problem

We obtain a 3-approximation for points in the plane as follows.

(1) For each value of k, $k = 1, \ldots, n$, we find a shortest possible connected m-guillotine subdivision, rooted at r, spanning k or more points. We tabulate the lengths of the resulting graphs, for each k.

(2) For each value of k, $k = 1, \ldots, n$, and for each vertex v, we find a shortest possible connected m-guillotine subdivision, rooted at v, spanning k or more points; if the resulting graph does not contain r, then we add the vertex r and the edge rv to the graph. We tabulate the lengths of the resulting graphs, for each k.

(3) Among the graphs tabulated, the algorithm selects a graph with the maximum number of points and whose total length is less than the specified bound B. The shortest tree spanning the sites in this subgraph is then output.

In steps (1) and (2), the algorithm tries every possible value of k, since the number of vertices spanned by an optimal solution to the tree-orienteering problem is not known. Also, since any tree spanning k vertices can be transformed into an m-guillotine subdivision spanning k vertices with only a small increase in total length ([23]), in step (1), the algorithm searches for a shortest connected m-guillotine subdivision spanning k vertices including the root r. Step (2) is not an obvious step; the enumeration in this step is needed, as shown in the proof below. The goal of this step is to search for additional "good" trees that span k (or $k+1$) vertices, including the root. This is achieved by searching for trees rooted at an arbitrary vertex v (for all possible vertices v) and spanning k vertices and then adding the edge rv to it. Since such trees can also be transformed into m-guillotine subdivisions spanning the same set of vertices, the algorithm looks for a shortest subdivision spanning k vertices including vertex v and then adds edge rv, if neccessary. Step (3) is a straightforward step that invloves finding a shortest connected subgraph (i.e., tree) spanning the sites in the best m-guillotine subdivision found in one of the earlier steps.

The general approach used above is also used in other algorithms that follow in this paper. The approach consists of three steps: (a). showing that any optimal geometric network satisfying a property $\mathcal{P}$ can be transformed into an m-guillotine subdivision that satisfies property $\mathcal{Q}$; (b). applying dynamic programming to compute in polynomial time a shortest m-guillotine subdivision satisfying property $\mathcal{Q}$; and then (c). showing that any m-guillotine subdivision satisfying property $\mathcal{Q}$ can be mapped back into a network satisfying property $\mathcal{P}$. In the above rooted tree-orienteering problem, property $\mathcal{P}$ is that the network is a tree spanning k vertices and having total length at most B, while property $\mathcal{Q}$ is that the network is a connected m-guillotine subdivision spanning k vertices.

Finally, we note that, in the above algorithm, it will suffice to set $m = 2$. Let T^* denote an optimal rooted tree, spanning the maximum number, $n(T^*)$, of points, while having weight at most B. Now, we claim that:

Lemma 1 *Among the graphs tabulated of types (1) and (2), there must be one whose weight is less than B, while the cardinality, k, of the point set spanned is at least $n(T^*)/3$.*

Proof. By standard results on separators in trees (e.g., see [26], Theorem 9.1, page 150), we know that there exists a partitioning of the optimal tree T^* into two subtrees, T_1 and T_2, sharing a common vertex v of T^*, so that $(2/3)n(T^*) \geq n(T_i) \geq (1/3)n(T^*)$. Without loss of generality, we assume that $r \in T_1$. We now consider two cases:

(i) Case: $w(T_1) - d(r,v) > w(T_2)$

Let T' be the union of $T_{2,G}$ and the segment rv, where $T_{2,G}$ is an m-guillotine subdivision containing T_2. By Theorem 3.3 of Mitchell [23], we know that there exists an m-guillotine subdivision, $T_{2,G}$ so that

$$w(T_{2,G}) \leq (1+\epsilon)w(T_2),$$

where $\epsilon = \frac{\sqrt{2}}{m}$, which implies that

$$\begin{aligned} w(T') &\leq (1+\epsilon)w(T_2) + d(r,v) \\ &< \epsilon w(T_2) + w(T_1) \\ &< w(T_2) + w(T_1) \\ &= w(T^*) \leq B \end{aligned}$$

where we assume that $m \geq 2$, so that $\epsilon < 1$. Thus, T' will be among the subdivisions considered in case (2) of the algorithm: The algorithm will enumerate a tree having the same number of vertices as T', while containing the root r and having weight at most $w(T')$, which, as shown above, is at most B.

(ii) Case: $w(T_1) - d(r,v) \leq w(T_2)$

Let $T'' = T_{1,G}$ be an m-guillotine subdivision containing T_1, and let $\epsilon = \frac{\sqrt{2}}{m}$. Again, by Theorem 3.3 of Mitchell [23], we know that there exists an m-guillotine subdivision, $T_{1,G}$ so that

$$w(T_{1,G}) \leq (1+\epsilon)w(T_1).$$

However, it turns out that the above inequality is not strong enough for our purposes here. Theorem 4 (see Section 2.4 below) is a strengthening of Theorem 3.3 of Mitchell [23]. Corollary 1 of Theorem 4 proves the following inequality:

$$w(T_{1,G}) \leq d(r,v) + (1+\epsilon)(w(T_1) - d(r,v)).$$

With this result, we then obtain

$$\begin{aligned} w(T'') = w(T_{1,G}) &\leq d(r,v) + (1+\epsilon)(w(T_1) - d(r,v)) \\ &\leq d(r,v) + 2(w(T_1) - d(r,v)) \\ &= w(T_1) + w(T_1) - d(r,v) \\ &\leq w(T_1) + w(T_2) = w(T^*) \leq B, \end{aligned}$$

where we have again assumed that $m \geq 2$, so that $\epsilon < 1$. Thus, T'' will be among the trees of type (1) considered by the algorithm.

In conclusion, both T' and T'' are among the trees considered in cases (1) and (2) of the algorithm; thus, the algorithm enumerates trees having at least $n(T^*)/3$, while having weight at most B. □

Theorem 1 *There is a 3-approximation polynomial-time algorithm for the rooted tree-orienteering problem on a set of points in the plane.*

2.2 Rooted Cycle-Orienteering Problem

We obtain a 2-approximation for points in the plane as follows. The algorithm computes for each value of k, $k = 1, \ldots, n$, a shortest possible connected "bridge-doubled" m-guillotine subdivision that includes the root vertex r and at least $k-1$ other points, and where every vertex that is not on a bridge has degree two. It then extracts a tour from each such subdivision, using the property that bridge-doubling allows one to obtain a subset of the edges which is Eulerian (as outlined in Section 4.2 of Mitchell [23]). The algorithm tabulates the lengths of the resulting tours for each k, and among the tours with length bounded by B, the algorithm selects one having the maximum number of vertices.

In the algorithm, it will suffice to set $m \geq 3$ (so that $\epsilon = 2\sqrt{2}/m < 1$). Let T^* denote an optimal tour visiting the maximum number, $n(T^*)$, points, while having weight at most B. Now, we claim that:

Lemma 2 *Among the tours tabulated by the algorithm described above, there must be one whose weight is less than B, while the cardinality, k, of the point set visited is at least $n(T^*)/2$.*

Proof. The length, $w(T^*)$, of an optimal tour, T^*, is bounded by B. Let v be a point on the tour (not necessarily a vertex) such that the points r and v partition the tour into two paths of weight $w(T^*)/2$. Let the two paths be called T_1 and T_2. Without loss of generality, assume that the path T_1 has at least $n(T^*)/2$ vertices on it.

Let T' be the union of T_1 and the segment rv. Let T'_G be a (bridge-doubled) m-guillotine subdivision containing T'. Once again, we need a stronger version of Theorem 3.3 from Mitchell [23]. Here, since T' contains a tour on its induced vertices, we apply Corollary 1 from Section 2.4 below, which provides the appropriate strengthening. Thus, we have:

$$\begin{aligned} w(T'_G) &\leq w(T') + \epsilon(w(T') - 2d(r,v)) \\ &= w(T_1) + d(r,v) + \epsilon(w(T_1) - d(r,v)) \\ &= (1+\epsilon)w(T_1) + (1-\epsilon)d(r,v) \\ &\leq (1+\epsilon)w(T_1) + (1-\epsilon)w(T_1) = 2w(T_1) = B \end{aligned}$$

Although v may not be a vertex, it is clear that there exists an m-guillotine subdivision T''_G that contains the same set of vertices as T'_G and with length no more than that of T'_G. Thus, T''_G will be among the tours considered by the algorithm; we will obtain a tour visiting as many vertices as T''_G, while having weight at most B. □

Theorem 2 *There is a 2-approximation polynomial-time algorithm for the rooted cycle-orienteering problem on a set of points in the plane.*

2.3 Rooted Path-Orienteering Problem

The algorithm for the path-orienteering problem is very similar to the ones for the cycle- and tree-orienteering problem. As with the case of cycles, we use bridge-doubled m-guillotine subdivisions in the algorithm, in order to be able to recover a path from an Eulerian subgraph; now, we also require that r have degree one, if it is not on a bridge. Also, since an optimal path can be split into just *two* subpaths, each with at least $n(T^*)/2$ vertices, we obtain a performance guarantee of 2 for rooted path-orienteering, instead of 3, as in the tree case.

Theorem 3 *There is a 2-approximation polynomial-time algorithm for the rooted path-orienteering problem on a set of points in the plane.*

2.4 A Strengthened m-Guillotine Subdivision Theorem

We now supply a theorem on m-guillotine subdivisions, which strengthens the original analysis in [23]. The crucial new aspect to the theorem is that, when converting an arbitrary subdivision into an m-guillotine subdivision, there is some portion of the length of the original subdivision that does not need to be "charged." This allows us, in the corollary below, to bound the increase in length (between an original subdivision and its guillotine version) by a small fraction of the *difference* between the length of the original subdivision and the length of an appropriate subgraph that is known to exist in the subdivision.

First, we need some notation. We consider a line segment pq to have two *sides* — a top side, and a bottom side. For a set E of line segments, we say that the top side of a segment pq on an edge of E is *i-exposed above* if there are exactly i connected components in the intersection of E and the upward-pointing ray from any point on pq. (The ray includes its endpoint, so that the intersection with pq is counted among the i components.) See Figure 2.4 for an example of a portion of E that is 2-exposed above. If there are exactly i connected components in the intersection of E and the rightward-pointing ray from any point on pq, then the top (resp., bottom) side of pq is said to be *i-exposed right*, if pq has negative (resp., positive) slope. We similarly define i-exposed *below* and i-exposed *left*. Let $\xi^{(m)}(E)$ be the sum of the lengths of all the sides of subsegments of E that are i-exposed in some direction (above, below, left, or right), for some $i \leq m$. Since we distinguish between the sides of a segment, it is possible that the length of pq is counted twice in the total $\xi^{(m)}(E)$ (e.g., if the top side of pq is i-exposed above *and* the bottom side is i'-exposed below, for $i, i' \leq m$).

Theorem 4 *Let S be a polygonal subdivision, with edge set E, of length L. Then, for any positive integer m, there exists an m-guillotine subdivision, S_G, of length at most $L + \frac{\sqrt{2}}{m}(L - \frac{\xi^{(m)}(E)}{2})$ whose edge set, E_G, contains E.*

Proof. (Sketch) We follow much of the proof of Mitchell [23], while making use of the fact that the portion of E that is within m levels of the top (resp., bottom, left, right) of the bounding box of E is never "charged" from above (resp., from the bottom, left, right). Thus, of the total side length $2L$ for E, there is side length $\xi^{(m)}(E)$ that never gets charged. Hence, the total length of all bridges constructed in the proof of [23] is at most $\frac{\sqrt{2}}{2m}(2L - \xi^{(m)}(E))$. □

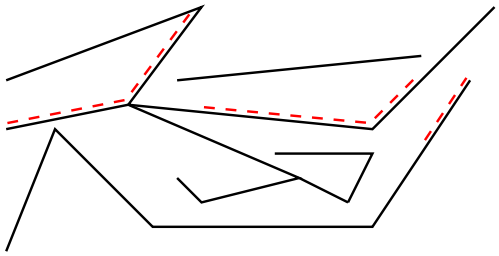

Figure 1: The portion of the tops of the edge set E that is 2-exposed above is highlighted.

The following corollary is required in proofs from Section 2.1, Section 2.3, and Section 2.2 above.

Corollary 1 *Let S be a polygonal subdivision, with edge set E, of length L. If S connects two vertices r and v in the subdivision, then, for any positive integer m, there exists an m-guillotine subdivision, S_G, whose edge set contains E, and is of length at most $L + \frac{\sqrt{2}}{m}(L - d(r,v))$. Furthermore, if S contains a cycle through the vertices r and v, then, for any positive integer $m \geq 2$, there exists an m-guillotine subdivision, S_G, whose edge set contains E, and is of length at most $L + \frac{\sqrt{2}}{m}(L - 2d(r,v))$ (or, $L + \frac{2\sqrt{2}}{m}(L - 2d(r,v))$, in the case of bridge-doubled m-guillotine subdivisions)*

Proof. (Sketch) The two statements in the corollary follow from Theorem 4, after showing the following: if S connects vertices r and v, then $\xi^{(m)}(E) \geq \xi^{(1)}(E) \geq 2d(r,v)$; if S contains a cycle involving the vertices r and v, and $m \geq 2$, then $\xi^{(m)}(E) \geq \xi^{(2)}(E) \geq 4d(r,v)$. In particular, it is not hard to show that for a simple polygon P, $\xi^{(1)}(P)$ is at least as large as the perimeter of the convex hull of P. □

3 Unrooted Orienteering Problems

The following observation was made in [7], for the cycle-orienteering problem. A similar proof holds also for the path and tree versions:

Theorem 5 *Given a c-approximation for the k-TSP we can obtain a $2c$-approximation for the unrooted orienteering problem (tree-, path-, or cycle-orienteering).*

Proof. We first prove the cycle-orienteering bound: For all $k = 1, 2, \ldots, n$ find T_k an approximate k-TSP. Let k be the number of points such that $T_k \leq cB$ and $T_{k+1} > cB$. Take the cycle T_k and break it into $2c$ pieces of length at most $B/2$ each. Take the piece that contains the most points, double it to create a cycle of length at most B containing at least $k/(2c)$ points. Note that since $T_{k+1} > cB$ we must have that the length of an optimal cycle of $k+1$ points $T^*_{k+1} > B$, therefore the optimal solution to the orienteering problem with bound B visits at most k points.

The proof for the path- and tree-orienteering problems is similar: For all $k = 1, 2, \ldots, n$ find T_k an approximate k-TSP. Let k be the number of points such that $T_k \leq 2cB$ and $T_{k+1} > 2cB$. Take the cycle T_k and break it into $2c$ pieces of length at most B each. Take the piece that contains the most points, it is a path, therefore also a tree of length at

most B containing at least $k/(2c)$ points. Note that since $T_{k+1} > 2cB$ we must have that the optimal cycle of $k+1$ points $T^*_{k+1} > 2B$, and hence the best path and the best tree on $k+1$ points are of length $> B$, and therefore the optimal solutions to the path- and tree-orienteering problems with bound B visit at most k points. □

Remark. We note that the method in the proof of the above theorem does not apply to the *rooted* cases.

Garg's [14] $c = 3$ bound for metric spaces for the k-TSP thus yields an approximation factor 6 for the unrooted tree-, path-, and cycle-orienteering problems in metric spaces. The PTAS of Mitchell [23] or Arora [4] imply $c = 1 + \epsilon$, and therefore an approximation factor $2 + \epsilon$ for the unrooted tree-, path-, and cycle-orienteering problems for points in the plane. Next, we improve these results.

3.1 Unrooted Tree-Orienteering

We begin with a result on the geometric version of the problem:

Theorem 6 *There is a 2-approximation polynomial-time algorithm for the unrooted tree-orienteering problem on a set of points in the plane.*

Proof. Our algorithm begins by computing a $(1+\epsilon)$-approximate k-MST, for each of the n possible values of k ($k = 1, 2, \ldots, n$); this can be done in polynomial time, using the algorithms of Mitchell [23] or Arora [4]. Then, among these n trees, we simply output the maximum cardinality (maximum k) tree whose weight is at most B.

We now argue that this algorithm yields a tree having at least $\lceil k^*/2 \rceil$ vertices, where k^* is the optimal value of k (the maximum number of points that can be spanned with a tree of weight at most B).

For each value of $k = 1, 2, \ldots, n$, let B_k be the length of an *optimal* k-MST, and let A_k be the length of the approximately optimal tree produced by the algorithm. We know that $A_k \leq B_k(1+\epsilon)$, for each value of k. By Theorem 9 (below), we know that $B_{\lceil k/2 \rceil} \leq (2/3)B_k$. If we choose ϵ such that $\epsilon < 1/2$, then it is clear that $A_{\lceil k/2 \rceil} \leq B_{\lceil k/2 \rceil}(1+\epsilon) \leq (2/3)B_k(1+\epsilon) < B_k$, for all k. Thus, since k^* is the optimal value of k, meaning that $B_{k^*} \leq B < B_{k^*+1}$, we know that $A_{\lceil k^*/2 \rceil} < B_{k^*} \leq B$. This implies that our algorithm will select a tree having a value of k that is *at least* as large as $\lceil k^*/2 \rceil$. □

Next we provide a 5-approximation algorithm for graphs, improving the previous factor of 6, while removing the requirement that the edge lengths satisfy the triangle inequality.

Theorem 7 *There exists a 5-approximation algorithm for the (unrooted) tree-orienteering problem in an edge-weighted graph (even without edge lengths satisfying the triangle inequality).*

Proof. The algorithm remains the same as in the proof of the previous theorem. However, no PTAS is known for this problem. There exists a 2.5-approximate algorithm for the k-MST problem [6].

For each value of $k = 1, 2, \ldots, n$, let B_k be the length of an *optimal* k-MST, and let A_k be the length of the approximately optimal tree produced by the algorithm. We know that $A_k \leq (5/2)B_k$, for each value of k. By Theorem 10 below, with $K = 5/2$, we know that $B_{\lceil k/5 \rceil} \leq (2/5)B_k$. Hence, $A_{\lceil k/5 \rceil} \leq (5/2)B_{\lceil k/5 \rceil} \leq (2/5)(5/2)B_k = B_k$, for all k. Thus, since k^* is the optimal value of k, meaning that $B_{k^*} \leq B < B_{k^*+1}$, we know that $A_{\lceil k^*/5 \rceil} \leq B_{k^*} \leq B$. This implies that our algorithm will select a tree having a value of k that is *at least* as large as $\lceil k^*/5 \rceil$. □

3.2 Unrooted Path- and Cycle-Orienteering Problems

Our improvement to the previously known approximation bounds is made in the geometric case, where, using the results on the *rooted* version, we achieve a factor 2, improving the previous bound of $2 + \epsilon$. We simply apply the rooted result for each choice of root. (We remark that our combinatorial tools (of the next section) do not lead to improved bounds.)

Theorem 8 *There is a 2-approximation polynomial-time algorithm for the unrooted path- and cycle-orienteering problems on a set of points in the plane.*

3.3 Combinatorial Tools

(Some proofs are deferred to the Appendix.)

Lemma 3 (Number-Partition Lemma) *If S is a set of n real numbers $x_1, x_2, \ldots, x_n$ such that their sum is B and $x_i < B/3, \forall i = 1, 2, \ldots, n$, then there exists a partition of S into two subsets, S_1 and S_2, such that $B/3 \leq \sum_{x_j \in S_i} x_j \leq 2B/3, i = 1, 2$.*

Lemma 4 (Tree-Partition Lemma) *Let T be an edge-weighted tree. The following statements are true:*

1. *There exists a partition of the edges of T into an edge e and two subtrees T_1 and T_2 such that e is incident on both the subtrees, and $w(T_i) < w(T)/3$, $i = 1, 2$ (so $w(e) > w(T)/3$); OR*
2. *There exists a partition of the edges of T into two subtrees T_1 and T_2 such that $w(T)/3 \leq w(T_i) \leq 2w(T)/3$, $i = 1, 2$.*

Proof. See Appendix. □

Theorem 9 *Given an edge-weighted tree T spanning n vertices, the following statements are true:*

1. *There exists a subtree T' of T with $w(T') \leq 2w(T)/3$ and spanning at least $n/2$ vertices, AND*
2. *There exists a subtree T' of T with $w(T') \leq w(T)/2$ and spanning at least $n/3$ vertices.*

Proof. See Appendix. □

We generalize Theorem 9 as follows.

Theorem 10 *Given an edge-weighted tree T spanning n vertices, and any $K > 1$, there exists a subtree T' of T with $w(T') \leq w(T)/K$ and spanning at least $n/(2K)$ vertices.*

Proof. Start with the tree T spanning n vertices. Now apply the partition lemma on T. If the first case holds, then among the two subtrees T_1 and T_2 "pick" the subtree with more vertices. If the second case holds, then "pick" the subtree with the larger ratio of number of vertices to the total weight. If the subtree "picked" has weight at most $w(T)/K$, then return it. If the subtree "picked" has weight larger than

$2w(T)/K$, then iterate the process with the "picked" subtree. Let the subtree at the end of the j-th iteration be denoted by $T^{(j)}$. Let the above process terminate after $i-1$ iterations and let $T^{(i-1)}$ be the resulting tree with weight at most $2w(T)/K$.

The idea here is that whenever the partition lemma is applied, it produces a subtree whose ratio of number of vertices to the total weight is no less than that at the start of the iteration. Let $T_1^{(j)}$, $T_2^{(j)}$ be the two subtrees of $T^{(j)}$, and assume without loss of generality that $n(T_1^{(j)})/w(T_1^{(j)}) \geq n(T_2^{(j)})/w(T_2^{(j)})$, then by cross multiplying we get

$$\frac{n(T_1^{(j)})}{w(T_1^{(j)})} \geq \frac{n(T_1^{(j)}) + n(T_2^{(j)})}{w(T_1^{(j)}) + w(T_2^{(j)})} = \frac{n(T^{(j)}) + 1}{w(T^{(j)})}.$$

Therefore, since the ratio of the the number of vertices to the weight never decreases, $n(T^{(i-1)}) \geq n \cdot w(T^{(i-1)})/w(T) \geq n/K$.

The last step of the algorithm has two cases. First, if $w(T^{(i-1)}) \leq 3w(T)/(2K)$ then by the first part of Theorem 9, there exists a subtree T^i such that

$$w(T^i) \leq \frac{2w(T^{(i-1)})}{3} \leq \frac{w(T)}{K},$$

with $n(T^i) \geq n(T^{(i-1)})/2 \geq n/(2K)$. On the other hand, if $3w(T)/(2K) < w(T^{(i-1)}) \leq 2w(T)/K$, then by the second part of Theorem 9, there exists a subtree T^i such that

$$w(T^i) \leq \frac{w(T^{(i-1)})}{2} \leq \frac{w(T)}{K},$$

with $n(T^i) \geq n(T^{(i-1)})/3 \geq n/(2K)$. □

In the Appendix (Lemmas 6 and 7), we show that the bounds above are tight for the metric case (for $K > 2$, in Theorem 10).

4 Generalizations and Extensions

4.1 Multiply-Rooted Orienteering

In the multiply-rooted orienteering problems, we are given, in addition to the length bound B, a set R of $\rho \geq 1$ required *root* sites (they must be visited by the network) in addition to the n original sites, S. The goal is to design a network of length at most B that visits all ρ of the root sites and that maximizes the number of non-root sites visited by the network.

Since our results for rooted versions of the orienteering problem are strongly based on geometric methods, we again restrict ourselves to the Euclidean plane.

The multiply-rooted tree-orienteering problem is closely related to the (planar) Euclidean Steiner tree problem, which is known to be NP-hard [13]. In the Steiner tree problem, one is to determine a tree of minimum total length whose vertices are a *superset* of a given set of points. The hardness of the Steiner tree problem implies that it is NP-hard to decide if there exists a tree spanning all of the given set, R, of roots, whose length is at most B, since this amounts to asking if the length, L^*, of a minimum Steiner tree satisfies $L^* \leq B$.

One might ask whether the problem becomes "easier" if we are told that $B > L^*$. We show that even for such instances, if we can approximate the multiply-rooted tree-orienteering problem within a constant factor, then we can solve the Euclidean Steiner tree problem exactly, within the same time bound. Hardness also applies to approximating the path and cycle versions of the problem.

Theorem 11 *Unless P=NP, there is no polynomial-time algorithm achieving a constant-factor approximation of the number of additional (non-root) sites visited by a multiply-rooted tree (or cycle or path) of length at most B, where B is known to exceed the length of a Steiner tree on the set of roots.*

Proof. We give here the proof for the tree version of the problem; proofs for the cycle and path versions are similar, from Euclidean TSP. Given an instance of the Euclidean Steiner tree problem on a set P of points, we create an instance of the tree-orienteering problem in which the set of roots is $R = P$. For the Steiner tree problem, we must decide if $L^* \leq L$, where L^* is the length of the minimum Steiner tree on R. We add one additional non-root site v, at distance $B - L$ from a point $p \in R$ on the convex hull of R (so that the distance of v to R is minimized at p). Clearly, a tree of length at most B that visits v, as well as all roots, exists if and only if a Steiner tree of length at most L exists for the points R. Thus, if $L^* \leq L$, then a c-approximation algorithm for tree-orienteering must return a tree that includes v; otherwise, it may return a tree with zero additional (non-root) points. □

Remark. We note that the hardness proof applies also to the problem of approximating the maximum *total* number of sites visited (including the roots), by replacing v with many copies of itself.

We obtain a 3-approximation for the multiply-rooted tree-orienteering problem, provided the number, ρ, of roots is *constant*. (The running time is $O(n^{O(\rho)})$.) Additionally, we obtain 2-approximations for the path and cycle versions of the problem.

Theorem 12 *Assuming that the number (ρ) of roots is constant, there is a polynomial-time 2-approximation (resp., 3-approximation) algorithm for the multiply-rooted path- and cycle-orienteering problems (resp., tree-orienteering problem) on a set of points in the plane.*

The proof of this theorem is based on some of the same ideas as in Theorems 1, 3, and 2, but with the application of Corollary 2 below.

We concentrate here only on the tree-orienteering case. The algorithm does the following: For each choice of

(a). integer k, $k = 1, \ldots, n$,

(b). site v,

(c). partition of R into two sets, R_1 and R_2,

we find a shortest possible connected m-guillotine subdivision (with $m \geq \rho - 1$), visiting site v, spanning k or more non-root sites, and spanning all of the roots R_1. We then append this tree to the minimum (Steiner) tree spanning $\{v\} \cup R_2$, and tabulate the lengths of all such trees. The tree whose length is at most B that maximizes the number of sites visited is a tree that we claim approximates the multiply-rooted tree-orienteering problem.

Lemma 5 *Among the graphs tabulated by the algorithm, there must be one whose weight is less than B, while the cardinality of the point set spanned is at least $n(T^*)/3$.*

Proof. As in the proof of Lemma 1, we know that there exists a partitioning of an optimal tree T^* into two subtrees, T_1 and T_2, sharing a common vertex v of T^*, so that $(2/3)n(T^*) \geq n(T_i) \geq (1/3)n(T^*)$. Let S_i denote the Steiner tree spanning the roots that are contained in subtree T_i.

Without loss of generality, we may assume that $w(T_1) - w(S_1) \leq w(T_2) - w(S_2)$. Now, consider the tree $T' = T_{1,G} \cup S_2$, where $T_{1,G}$ is an m-guillotine subdivision, with $m \geq \rho - 1$, containing the edge set of T_1. By Corollary 2, $w(T_{1,G}) \leq w(T_1) + \epsilon(w(T_1) - w(S_1))$. Then, T' spans all of R, and it is among the class of trees considered by the algorithm. Thus, we have only to show that its weight is bounded by B:

$$\begin{aligned} w(T') &= w(T_{1,G}) + w(S_2) \\ &\leq w(T_1) + \epsilon(w(T_1) - w(S_1)) + w(S_2) \\ &\leq w(T_1) + \epsilon(w(T_2) - w(S_2)) + w(S_2) \\ &\leq w(T_1) + (w(T_2) - w(S_2)) + w(S_2) \\ &= w(T_1) + w(T_2) \leq B \end{aligned}$$

where we assume that $m \geq 2$, so that $\epsilon < 1$, and we have used Corollary 2, below, to obtain the first inequality. □

The following corollary to Theorem 4 is based again on a more careful analysis of the charging scheme in [23], together with the following generalization of the observation used in Corollary 1: If E spans the set R of ρ roots, then E must contain a (Steiner) spanning tree of R; thus, the total $\leq (\rho-1)$-exposed side length, $\xi^{(\rho-1)}(E)$, of E must be at least twice the length of the Steiner minimum spanning tree of R.

Corollary 2 *Let S be a polygonal subdivision, with edge set E, of length L, If E spans the set, R, of ρ roots, then, for any positive integer $m \geq \rho - 1$, there exists an m-guillotine subdivision, S_G, whose edge set contains E, and is of length at most $L + \frac{\sqrt{2}}{m}(L - L^*(R))$, where $L^*(R)$ is the length of a Steiner minimum spanning tree of R.*

4.2 Polygonal Sites

In the case that the n sites are given to us as a collection of *regions* rather than points, we get a problem closely related to the "TSP with Neighborhoods" (TSPN) problem. We assume that the regions are given as a collection of n simple polygons, having a total of N vertices.

For the TSPN, Arkin and Hassin [1] have obtained $O(1)$-approximation algorithms for "well behaved" (possibly overlapping) regions (e.g., regions are disks or have roughly equal-length and parallel diameter segments), while Mata and Mitchell [19] have obtained an $O(\log n)$-approximation algorithm for n general (possibly overlapping) regions, based on "guillotine rectangular subdivisions".

We prove the following theorem, giving the first approximation results for the orienteering version of the problem:

Theorem 13 *There is an $O(\log n)$-approximation algorithm for the tree-orienteering (and path- and cycle-orienteering) problems on a set of polygonal sites in the plane. The running time is polynomial in n and N.*

Proof. (Sketch) We give here the proof only for the tree version of the problem. Let T^* denote an optimal tree, spanning the maximum number, $n(T^*)$, sites, while having weight at most B.

Our approximation algorithm is to tabulate, for each value of k, $k = 1, \ldots, n$, a shortest possible connected *guillotine rectangular subdivision* spanning k or more regions. (This can be done in time polynomial in n and N, using dynamic programming, as in [19].) We then select, from among these, the subdivision that visits the maximum number k of regions, subject to its weight being less than the bound B.

We now have to prove that, among the subdivisions tabulated, there must be one, T, whose weight is less than B, while the cardinality, k, of the set of regions spanned is at least $n(T^*)/O(\log n)$. Our proof is based on our earlier combinatorial theorem, Theorem 10, which guarantees that there exists a subtree, T', of T^*, with $w(T') \leq w(T^*)/C \log n$ and spanning at least $n(T^*)/2C \log n$ regions, for any constant C. Then, using the fact ([19]) that any rectilinear edge set is contained within the edge set of a guillotine rectangular subdivision, having length within factor $O(\log n)$, we get that there must exist a guillotine rectangular subdivision, G, spanning the same set of regions as does T' (and thus, spanning at least $n(T^*)/2C \log n$ regions), such that the length of G is at most $w(T') \cdot C \log n \leq w(T^*) \leq B$, for some constant C. This proves that our algorithm will indeed discover a tree spanning at least $n(T^*)/O(\log n)$ regions. □

5 Conclusion

An outstanding open problem that remains is to obtain an approximation algorithm (or prove that none exists) for the rooted orienteering problems in graphs.

Also, it is interesting to note that, in the geometric case, our current best bound (2) for the rooted cycle- and path-orienteering problems is better than the bound (3) for the rooted tree-orienteering problem. Can the tree version be improved? (In contrast, in the unrooted graph version, our methods give a factor of 5 for trees and 6 for cycles and paths.) Is the factor 2 best possible for the cycle and path versions?

Appendix

Proof of the Tree-Partition Lemma 4:

Assume that the first case does not happen, i.e., there does not exist a large weight edge e such that the edges of T can be partitioned into edge e and two subtrees T_1 and T_2 with $w(T_i) < w(T)/3, i = 1, 2$. We will then show that there must exist a partition of the edges of T into two subtrees T_1 and T_2 such that $w(T)/3 \leq w(T_i) \leq 2w(T)/3, i = 1, 2$. We display an algorithm that will, in fact, find such a partition.

The algorithm is as follows. Start at any vertex v with incident edges $e_1, e_2, \ldots, e_t$. Consider a partition of T into subtrees $T_i, i = 1, 2, \ldots, t$, such that subtree T_i includes edge e_i and all the subtrees share only one vertex in common, namely vertex v.

Case 1: If there exists a subtree T_i such that $w(T)/3 \leq w(T_i) \leq 2w(T)/3$, then the lemma is proved by the following argument. Let T_1 be the subtree T_i. Let T_2 be the union of the other subtrees after identifying vertex v. The subtrees T_1 and T_2 satisfy the inequality $w(T)/3 \leq w(T_i) \leq 2w(T)/3, i = 1, 2$.

Case 2: If there exists no subtree T_i such that $w(T)/3 \leq w(T_i)$, then by Lemma 3, there exists a partition of the subtrees into two sets such that the sum of the weights of the subtrees in each of the sets lies between $w(T)/3$ and $2w(T)/3$.

Case 3: If there exists a subtree T_i such that $w(T_i) > 2w(T)/3$, and if the edge e_i is incident on vertices v and v', then we restart the algorithm from vertex v'.

It is clear that if Cases 1 or 2 occur at any time, the algorithm terminates after correctly finding the subtrees T_1 and T_2 needed for the proof of the lemma. We are left to show that Case 3 can occur only a finite number of times. As long as the algorithm does not return to a vertex v, it is bound to hit a leaf and terminate in at most n steps. If the algorithm ever returns to vertex v from vertex v', it will oscillate forever between vertices v and v'. We will now show that this cannot happen. For the sake of contradiction, assume that the algorithm oscillates between adjacent vertices v and v'. Let e be the edge connecting them. Let the union of all subtrees incident on v (v') that do not include edge e be called T_{i1} and T_{i2}. Define the subtrees $T_i = T_{i1} \cup \{e\}$ and $T_i' = T_{i2} \cup \{e\}$. Since the algorithm moves from vertex v to v', we know that $w(T_i) > 2w(T)/3$. Similarly, since the algorithm moves from vertex v' to v, we know that $w(T_i') > 2w(T)/3$. Since $w(T_{i1}) + w(T_i') = w(T) = w(T_{i2}) + w(T_i')$, we get that $w(T_{i1}) < w(T)/3$ and $w(T_{i2}) < w(T)/3$, contradicting our assumption that Case 1 does not occur. □

Proof of Theorem 9:

By the tree-partition lemma (Lemma 4), the tree T has one of two possible decompositions. If the first case occurs, then T can be partitioned into two subtrees (T_1 and T_2) and an edge with both subtrees of weight at most $w(T)/3$. Since T_1 and T_2 also partition the vertex set of T, one of them must contain at least $n/2$ vertices. Without loss of generality we assume that T_1 contains at least $n/2$ vertices. Then T_1 satisfies both the statements of the theorem.

If, on the other hand, the first case does not occur, then T can be partitioned into two subtrees (T_1 and T_2) with both subtrees of weight between $w(T)/3$ and $2w(T)/3$. Since one of them must contain at least $n/2$ vertices, this subtree must satisfy the first statement of the theorem. We are left only with proving the second statement of the theorem for this case. Without loss of generality assume that $w(T_1) \geq w(T_2)$. Thus $w(T_2) \leq w(T)/2$. If $n(T_2) \geq n/3$ vertices, then T_2 satisfies the requirements of the theorem. However, if $n(T_2) < n/3$, then $n(T_1) > 2n/3$. Now we apply the partition lemma on tree T_1.

If the first case occurs, then T_1 can be partitioned into two subtrees (T_{11} and T_{12}) and an edge, with both subtrees of weight at most $w(T_1)/3$. Let $n(T_{11}) \geq n(T_{12})$. Thus, $n(T_{11}) \geq n(T_1)/2 \geq (1/2)(2n/3) = n/3$. Also, $w(T_{11}) < w(T_1)/3 < w(T)/3$. Thus, T_{11} satisfies the requirements of the theorem.

Finally, if the first case does not hold for T_1, then T_1 can be partitioned into two subtrees, T_{11} and T_{12}, each of weight at most $2w(T_1)/3$. Without loss of generality, assume that $n(T_{11}) \geq n(T_{12})$. Thus $n(T_{11}) \geq n(T_1)/2 \geq (1/2)(2n/3) = n/3$. Also, $w(T_{11}) \leq 2w(T_1)/3 \leq (2/3)(2w(T)/3) < w(T)/2$. Thus, T_{11} satisfies the requirements of the theorem. □

Lemma 6 *For $K > 2$, there exists a metric space on a set S of $Kt + 1$ vertices such that any tree spanning at least $t+2$ of the vertices has total weight at least $2L/K$, where L is the weight of a minimum spanning tree of S. For $K = 2$, there exists a metric space on a set S of $2t$ vertices such that any tree spanning at least $t + 1$ of the vertices has total weight L, where L is the weight of a minimum spanning tree connecting S.*

Proof. For $K = 2$, consider a configuration of n points that consists of two groups of vertices (each with t vertices) where any two vertices in the same group are at distance 0 from each other and the distance between a pair of vertices in two different groups is L, which is also the length of a minimum spanning tree on the given vertices. Clearly, any tree that spans $t + 1$ vertices or more, must have length at least L.

For $K > 2$ we modify the construction slightly. Let s be a special vertex. Consider K groups of vertices (each with t vertices) where any two vertices in the same group are at distance 0 from each other and each of the vertices is at distance L/K from vertex s. The distance between a pair of vertices in two different groups is defined by the metric space and is thus $2L/K$. Any tree that spans $t+2$ vertices or more, must span vertices from at least two different groups and consequently must have length at least $2L/K$. □

Lemma 7 *There exists a set S of $3t+1$ points in the plane such that any tree spanning at least $t + 2$ of the vertices has total weight at least $L/\sqrt{3}$, where L is the weight of a minimum spanning tree connecting S.*

Proof. Let s be a special vertex. Consider 3 groups of vertices (each with t vertices) with each group located at the 3 corners of an equilateral triangle with s at its center. The distance from a corner of the triangle to its center is $L/3$. Any two points in the same group is at distance 0 from each other. The distance between a pair of vertices in two different groups is $L/\sqrt{3}$. □

The above lemma also shows that there exist configurations for which one needs a tree of weight at least $L/\sqrt{3}$ in order to span at least $n/2$ points.
