## Abstract

We present the first constant-factor approximation algorithm for a non-trivial instance of the optimal guarding (coverage) problem in polygons. In particular, we give an  $O(1)$ -approximation algorithm for placing the fewest point guards on a 1.5D terrain, so that every point of the terrain is seen by at least one guard. While polylogarithmic-factor approximations follow from set cover results, our new results exploit geometric structure of terrains to obtain a substantially improved approximation algorithm.

## 1 Introduction

For a geometric domain  $\mathcal{D}$ , the *optimal guarding (coverage) problem* is to determine the smallest number,  $k^*$ , of *guards* (e.g., points) that can be placed in  $\mathcal{D}$  so that each point of  $\mathcal{D}$  is *seen* by at least one guard. The optimal guarding problem is an instance of a set cover problem that is induced by a geometry setting. The many related problems, both combinatorial and algorithmic, fall into the general category known as *art gallery problems*, which have been studied extensively; see, e.g., [11, 13, 15, 16].

We give the first constant-factor approximation algorithm for a non-trivial instance of optimal guarding polygons. All prior approximation bounds are polylogarithmic in  $n$  and/or  $k^*$ .

The instance we study here is the (1.5D) *terrain guarding problem*, in which the input domain is the two-dimensional region above an  $x$ -monotone polygonal chain having  $n$  vertices. We restrict guards to be placed at points on the terrain; with no restriction on guard placement, a single guard (at a high enough altitude) suffices to see the terrain.

**Related Work.** The classical combinatorial result, the “art gallery theorem”, states that  $\lfloor n/3 \rfloor$  guards are sufficient, and sometimes necessary, to guard an  $n$ -vertex simple polygon [13]. Combinatorial results on the number of guards needed for various forms of guarding on terrains are given in [1].

The optimal guarding problem is known to be NP-hard, even if  $\mathcal{D}$  is a simple polygon [14]. Thus, efforts have concentrated on the approximability of optimal guarding problems. Ghosh [9] gave an  $O(\log n)$ -approximation for optimal coverage of a polygon by vertex guards, based on standard set cover results. Recent interest [5, 10] has focused on methods of efficiently applying the Brönnimann-Goodrich technique [2], which exploits finiteness of VC-dimension. Efrat and Har-Peled [5] obtain an  $O(\log k^*)$ -approximation algorithm for polygon guarding with vertex guards, using time  $O(n(k^*)^2 \log^4 n)$ , where  $k^*$  is the optimal number of vertex guards. Their technique can be applied to non-vertex guards, lying at points of a dense grid, adding to the running time a factor polylogarithmic in the grid density. (No approximation algorithm is known if the guards are completely unrestricted and all of the polygon is to be guarded.) Their results apply

also to polygons with holes and to 2.5D terrains, still with polylogarithmic approximation factors. Most recently, Cheong et al. [4] have shown how to place  $k$  guards in order to optimize (approximately) the total area seen by the guards.

Eidenbenz et al. [6, 8] have shown that it is APX-hard to solve the optimal guarding problem in simple polygons; thus, there exists an  $\epsilon > 0$  such that it is NP-hard to obtain a  $(1 + \epsilon)$ -approximation algorithm. They further show that guarding polygons with holes, as well as guarding 2.5D terrains, is as hard as set cover; these problems do not have polynomial-time algorithms with approximation ratio less than  $c \ln n$ , for some  $c > 0$ , unless  $P = NP$  (and do not have approximation ratio  $\frac{1-\epsilon}{12} \ln n$ , for any  $\epsilon > 0$ , unless  $NP \subset TIME(n^{O(\log \log n)})$ ). These hardness of approximation results are complemented by  $O(\log n)$ -approximation algorithms based on greedy set cover [7].

For 1.5D terrains, Chen et al. [3] claim that a modification of the hardness proof of [14] shows that the problem is NP-hard (details are omitted and are still to be verified). In the very restricted setting where all guards are to be placed at a constant altitude (above “sea level”, not above the terrain surface), the optimal guarding problem is readily solved in polynomial time (it reduces to a one-dimensional problem on intervals); in fact, it can be solved in linear time [6, 12].

**Motivation.** The terrain guarding problem arises in optimal placement of antennas for communication networks. We are motivated to study the problem in two dimensions, in an effort to understand better the much more difficult three-dimensional (2.5D) terrain guarding problem (which Eidenbenz shows has no better than a log-approximation). Further, the two-dimensional problem shows up as a subproblem in heuristics to solve the three-dimensional problem, and it arises directly in applications of coverage along a highway, security lamp and camera placement along walls and streets. In some applications, one only needs to cover a portion of the input domain; our results can be extended to yield an algorithm for covering a subset of the terrain surface optimally.

**Our Results.** Our main result is an efficient  $O(1)$ -approximation algorithm for the terrain guarding problem in two dimensions. Our results rely on developing several geometric properties of terrains, in order that our algorithm can exploit the special structure.

The majority of the difficulty in proving our main result is in showing that one can obtain a constant-factor approximation to the dominating set problem in graphs that can be realized as the visibility graph of the vertices of a terrain polygon (i.e., to the problem of placing vertex guards on a terrain in order to see all other vertices). It is then relatively straightforward to extend this result to applying to placing arbitrary guards on the terrain in order to guard all of the terrain.

It is worth noting that some natural and simple approaches to the problem do not yield  $O(1)$ -approximations: One can give examples showing a subset of vertices guarding  $T$ , without redundant vertices, that is arbitrarily bad with respect to optimal; similarly, simple sweep approaches that add guards “as needed” can be arbitrarily bad.

## 2 Preliminaries

Let  $T$  be a terrain of complexity  $n$  in the plane; more precisely, let  $T$  be an  $x$ -monotone polygonal curve specified by  $n$  vertices,  $v_1, \dots, v_i = (x_i, y_i), \dots, v_n$ , indexed in  $x$ -increasing order. We refer to the *terrain polygon*,  $P_T$ , which is the closed region of the plane bounded from below by  $T$  and from the sides by the upwards vertical rays emanating from  $v_1$  and  $v_n$ , respectively.

Let  $p = (p_x, p_y)$  and  $q = (q_x, q_y)$  be two points on the polygonal curve  $T$ . We say that  $p$  *sees*  $q$  (and  $q$  *sees*  $p$ ) if and only if the line segment  $\overline{pq}$  is contained in  $P_T$ . We write  $p < q$  if  $p$  is to the left of  $q$  (i.e.,  $p_x < q_x$ ). For any two vertices  $u, v \in T$  with  $u < v$ , the *subterrain*  $[u, v]$  of  $T$  is simply the portion of  $T$

between  $u$  and  $v$ . For a point  $p \in T$ , let  $L(p)$  (resp.,  $R(p)$ ) denote the leftmost (resp., rightmost) point on  $T$  that sees  $p$ . It is easy to see that  $L(p)$  and  $R(p)$  are necessarily vertices of  $T$ .

A *guard* is a point of  $P_T$  that we consider to be able to view (“guard” or “cover”) other points of  $P_T$ . A *terrain guard* is any point on  $T$ ; a *vertex guard* is a vertex of  $T$ .

The *must-guard set*,  $M$ , is a subset of  $P_T$  that we require to be seen by a set of guards. The *dominating set problem on terrains* (DSPT) is to compute a minimum-cardinality set of vertex guards for  $M = \{v_1, \dots, v_n\}$  equal to the vertex set of  $T$ . We spend most of our effort in obtaining an approximation algorithm for DSPT; then, we describe how this result extends to the case of terrain guards and to the case of  $M = T$ . (Note that a set of guards that sees  $M = T = \partial P_T$  necessarily sees all of  $P_T$ ; however, it is not the case that guarding the boundary of a general simple polygon  $P$  implies guarding the interior of  $P$ .)

We say that a subterrain  $[u, v]$  *can be guarded from the right* (resp., *left*) if there exists a set of vertex guards to the right (resp. left) of  $v$  that cover  $M \cap [u, v]$ .

A basic fact we exploit throughout is readily proved:

**Claim 2.1 (Order Claim)** *Let  $a < b < c < d$  be four points on  $T$ . If  $a$  sees  $c$  and  $b$  sees  $d$ , then  $a$  sees  $d$ .*

### 3 The Main Algorithm

In this section we present a constant-factor approximation algorithm for the dominating set problem on terrains (DSPT): Find a minimum-size subset  $G$  of vertices of  $T$ , such that each vertex of  $T$  is visible from one of the vertices in  $G$ .

We begin by computing the (upper) convex hull of  $T$ , denoted  $CH(T)$ . Notice that if  $m$  is the number of vertices in  $CH(T)$ , then at least  $\lfloor \frac{m}{2} \rfloor$  guards are needed in order to guard  $T$ . In the first stage, we thus place a guard at each vertex of  $CH(T)$ . Notice that if  $T'$  is a subterrain defined by two consecutive vertices of  $CH(T)$ , then no point in its interior is visible from outside  $T'$ . We therefore may consider each of the  $m - 1$  subterrains that are defined by the vertices of  $CH(T)$  separately (see Figure 1).

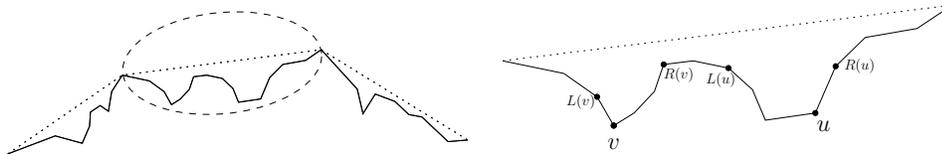

Figure 1: The overall structure of the algorithm.

Let  $T'' = [u, v]$  be a subterrain of  $T'$ . We say that  $T''$  *requires a local guard* if there exists a vertex  $w$  in the interior of  $T''$  that is not seen from  $(T' - T'') \cup \{u, v\}$ , or, in other words,  $u < L(w) < R(w) < v$ .

Let  $T'$  be one of the subterrains obtained from the first stage. In the second stage we partition  $T'$  into subterrains such that each of them does not require a local guard. We do this as follows. For each internal vertex  $v$  of  $T'$ , we compute the points (vertices)  $L(v)$  and  $R(v)$ . Let  $T(v)$  denote the subterrain  $[L(v), R(v)]$ . Viewing the subterrains  $T(v)$  as open horizontal intervals and considering only *minimal* intervals (i.e., intervals that do not contain other intervals), we compute a maximal set  $\mathcal{S}$  of disjoint subterrains. Let  $\mathcal{S}'$  be the complimentary set of subterrains; thus, any two consecutive subterrains in  $\mathcal{S}$  define at most one subterrain in  $\mathcal{S}'$ .

**Claim 3.1** *Let  $T''$  be a subterrain in  $\mathcal{S} \cup \mathcal{S}'$ . Then  $T''$  does not require a local guard.*

We place guards at the end vertices of the subterrains in  $\mathcal{S}$ . In addition, for each  $T'' \in \mathcal{S} \cup \mathcal{S}'$ , we place guards at the at most 4 vertices  $R(a_l), R(a_r), L(b_l), L(b_r)$ , where  $a_l$  (resp.,  $a_r$ ) is the leftmost (resp., rightmost) internal vertex of  $T''$  that is seen from the right of  $T''$ , and  $b_l$  (resp.,  $b_r$ ) is the leftmost (resp., rightmost) internal vertex of  $T''$  that is seen from the left of  $T''$ . Since  $|\mathcal{S}|/2$  is clearly a lower bound on the number of guards needed to guard  $T'$ , we only increase the number of vertices by a constant factor.

We now “solve” each of the subterrains in  $\mathcal{S} \cup \mathcal{S}'$  *separately*. Each such subterrain is considered to be a *base case*, in that it does not require a local guard, and is solved using the base-case algorithms detailed in Section 4. The *independence property* (based on Claims 3.2-3.3) shown below justifies this approach, i.e., that the subterrains in  $\mathcal{S} \cup \mathcal{S}'$  may be solved separately without hurting the approximation bound.

The overall structure of the algorithm is thus as follows.

- Given a terrain  $T$  compute its (upper) convex hull, place guards at the vertices of the convex hull, and solve each subterrain  $T'$  separately.
- Given a subterrain  $T'$  partition it into subterrains  $\mathcal{S} \cup \mathcal{S}'$ , as described above. For each subterrain  $T'' \in \mathcal{S} \cup \mathcal{S}'$ , place guards at the end vertices of  $T''$  and at the vertices  $R(a_l), R(a_r), L(b_l), L(b_r)$ , and solve the remaining unguarded fragments of  $T''$  separately, using the base-case algorithms detailed in Section 4.

### The independence property

Let  $T$  be a terrain, and let  $T_1, \dots, T_k$  be  $k$  disjoint subterrains of  $T$ . (Two subterrains may have a common end vertex.) Assume that the size  $l$  of an optimal solution for  $T_1 \cup \dots \cup T_k$  (by placing guards on  $T$ ) is greater or equal to  $k/c_1$ , for some constant  $c_1$ . And assume that for each subterrain  $T_i$ , we can compute a  $c_2$ -solution for (the yet unguarded fragments of)  $T_i$ , for some constant  $c_2$ . Then we can compute a  $c$ -solution for  $T_1 \cup \dots \cup T_k$ , for some constant  $c$ .

In this section we prove the claim above, which we refer to as the *independence property*. We begin by placing at most  $2k$  guards at the end vertices of the subterrains  $T_1, \dots, T_k$ .

**Claim 3.2** *Let  $r_1 < r_2 < \dots < r_m$  be the internal vertices of  $T_i$  that can be seen from the right of  $T_i$ . Then*

1.  $R(r_1) \geq R(r_2) \geq \dots \geq R(r_m)$ .
2. *If  $r_i$ , for  $1 < i < m$ , cannot be seen from  $R(r_m)$  or from  $R(r_1)$ , then it can only be seen (when viewing from the right of  $T_i$ ) from vertices in the interior of the subterrain  $[R(r_m), R(r_1)]$ .*

**Proof:** The first part follows immediately from the Order Claim. If  $R(r_2) > R(r_1)$ , then by the Order Claim  $r_1$  must see  $R(r_2)$ , which is impossible since  $r_1$  does not see beyond  $R(r_1)$ . Similarly,  $R(r_2) \geq R(r_3)$ , etc.

To prove the second part, assume that  $r_i$  (for some  $1 < i < m$ ) cannot be seen from  $R(r_m)$  or from  $R(r_1)$ . Then  $r_i$  cannot be seen from a vertex to the left of  $R(r_m)$  (and to the right of  $T_i$ ), since if  $r_i$  is seen from such a vertex, then, by the Order Claim, it is also seen from  $R(r_m)$ . Similarly,  $r_i$  cannot be seen from a vertex to the right of  $R(r_1)$ , since if it is seen from such a vertex, then, by the Order Claim,  $r_1$  is also seen from this vertex, which is impossible (by the definition of  $R(r_1)$ ).  $\square$

Put  $R(T_i) = [R(r_m), R(r_1)]$ , and let  $L(T_i)$  be the symmetric subterrain that is defined by considering the internal vertices of  $T_i$  that can be seen from the left of  $T_i$ .

**Claim 3.3** *Let  $T_i, T_j$  be two of the subterrains above, such that  $T_j$  lies to the right of  $T_i$ . Let  $R(T_i, j) \subseteq R(T_i)$  be the subterrain defined by only considering the internal vertices in  $T_i$  that can be seen from the right of  $T_j$ . Then  $R(T_i, j)$  and  $R(T_j)$  are disjoint, where the right end vertex of  $R(T_j)$  and the left end vertex of  $R(T_i, j)$  may coincide.*

**Proof:** Assume there is an internal vertex in  $T_i$  that can be seen from the right of  $T_j$ . (Otherwise,  $R(T_i, j)$  is empty.) Let  $u$  be the leftmost vertex in  $T_j$  that can be seen from the right of  $T_j$ . Then  $R(u)$  defines the right end vertex of  $R(T_j)$ . By the Order Claim, if  $v$  is any vertex in  $T_i$  that can be seen from the

right of  $T_j$ , then  $R(v) \geq R(u)$ . □

A symmetric claim can be formulated using the subterrains  $L(T_i)$  and  $L(T_j, i)$  instead of  $R(T_i, j)$  and  $R(T_j)$ , respectively.

We are now ready to continue the construction of a  $c$ -solution for  $T_1 \cup \dots \cup T_k$ . For each  $T_i$ , we place guards at the end vertices of the subterrains  $R(T_i)$  and  $L(T_i)$ . We have thus placed at most  $4k$  guards in this step (and at most  $6k$  guards in the first two steps). Next, for each  $T_i$  we compute a  $c_2$ -solution  $\mathcal{V}_i$  for (the yet unguarded fragments of)  $T_i$ . We claim that the at most  $6k$  guards of the first two steps together with the sets  $\mathcal{V}_i$  form a  $c$ -solution for  $T_1 \cup \dots \cup T_k$ .

Let  $\mathcal{V}_{opt}$  be an optimal solution for  $T_1 \cup \dots \cup T_k$ . Recall that we are assuming that  $|\mathcal{V}_{opt}| \geq k/c_1$ , for some constant  $c_1$ . Let  $U$  denote the set of at most  $4k$  vertices that are the end vertices of the subterrains  $R(T_i)$  and  $L(T_i)$ . Let  $v \in \mathcal{V}_{opt} - U$ . We observe that there is at most one subterrain  $T_i$  to the left of  $v$ , that has an internal vertex that is not seen by a vertex of  $U$  but is seen from  $v$ . If there are two such subterrains  $T_i$  and  $T_j$ , where  $T_j$  is to the right of  $T_i$ , then, by Claim 3.2,  $v$  is an internal vertex of both  $R(T_i)$  and of  $R(T_j)$ . More precisely,  $v$  is in  $R(T_i, j)$  (but not its right end vertex) and  $v$  is an internal vertex of  $R(T_j)$ . But this is impossible by Claim 3.3. Thus  $v$  can help guarding at most one subterrain to its left, at most one subterrain to its right, and possibly the subterrain in which it lies. Our construction replaces  $v$  with at most  $3c_2$  guards.

## 4 Base-Case Algorithms

Let  $T$  be a terrain with  $n$  vertices, and let  $\mathcal{G}$  be the subset of vertices of  $T$  where guards have already been placed. Let  $A$  be a subterrain of  $T$  that does not require a local guard, and let  $A'$  be the subset of vertices of  $A$  that cannot be seen by  $\mathcal{G}$ . We wish to compute a set of guards  $\mathcal{V}(A')$  located at vertices of  $T$ , some of which may be located within  $A$ , that together see all vertices in  $A'$ , and such that the size of  $\mathcal{V}(A')$  is within some constant factor of the size of an optimal such set of guards.

We distinguish between three base cases.

**(Case 0)** We require that  $\mathcal{V}(A')$  consist only of vertices that lie to the *left* of subterrain  $A$ .

**(Case 1)** We require that  $\mathcal{V}(A')$  consist only of vertices that lie *left or within* subterrain  $A$ .

**(Case 2)** We make no requirements of the set  $\mathcal{V}(A')$  of vertices of  $T$  that guard subterrain  $A$ .

Each subterrain  $T'' \in \mathcal{S} \cup \mathcal{S}''$  (see the previous section) is passed to the Case 2 algorithm, which in turn may pass it on to the Case 1 algorithm; see Figure 2.

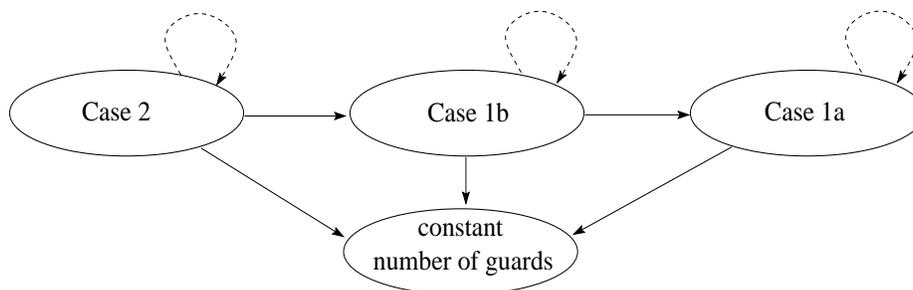

Figure 2: The program flow of the base case algorithms: A dashed line denotes a recursive call, while a solid line denotes a call to another (simpler) algorithm.

**Definition 4.1** Let  $T$  be a terrain and let  $\mathcal{G}$  be the subset of vertices of  $T$  where guards have already been placed. Let  $T'$  be the subset of vertices of  $T$  that cannot be seen by  $\mathcal{G}$ . We say that two subterrains  $T_1, T_2 \subset T$  are guard independent with respect to  $\mathcal{G}$  if the set of vertices of  $T$  that are seen by  $T_1 \cap T'$  and the set of vertices seen by  $T_2 \cap T'$  are disjoint. In other words,  $T_1$  and  $T_2$  are guard-independent subterrains if any guard  $g$  that can see a vertex in  $T_1 \cap T'$  cannot see a vertex in  $T_2 \cap T'$  and vice versa.

#### 4.1 Case 0

Let  $A$  be a subterrain of  $T$  such that it is possible to guard the (so far unguarded) vertices  $A'$  using only guards at vertices of  $T$  to the left of  $A$ . Our goal is to determine a minimum-cardinality such set of *left guards* for  $A'$ . In this specially constrained case, we are able to determine an *optimal* set,  $\mathcal{V}(A')$ , of guards, using the following algorithm:

While  $A'$  contains an unguarded vertex, do

Place a guard at  $L(a)$ , where  $a$  is the leftmost vertex in  $A'$  that is not yet guarded.

**Lemma 4.2** *The algorithm above computes an optimal subset of left guards for  $A'$ .*

**Proof:** When the algorithm locates a guard at vertex  $L(a)$ , no vertex to the left of  $L(a)$  can see  $a$  (by definition of  $L(a)$ ), and any vertex  $v$  to the right of  $L(a)$  (and still to the left of  $A$ ) that sees  $a$  is “dominated” by  $L(a)$  (by the Order Claim), in that a guard at  $L(a)$  will see any vertex of  $A'$  that  $v$  sees. We continue by induction.  $\square$

#### 4.2 Case 1

Let  $A = [a, b]$  be a subterrain that does not require a local guard, let  $A'$  be the subset of vertices of  $A$  that remain to be guarded, and assume that  $A'$  can be guarded from the left of  $A$ , that is, by placing guards only at vertices of  $T$  to the left of  $A$ .

In this case (Case 1), our goal is to compute a set of guards  $\mathcal{V}(A')$  for  $A'$  such that each guard in  $\mathcal{V}(A')$  is either to the left of  $A$  or within  $A$  (but not to the right of  $A$ ). We present a constant-factor approximation algorithm for computing a minimum-cardinality such set of guards.

We will need the following claim, which tells us that it does not make sense to place a guard within  $A$  if its sole purpose is to view rightwards.

**Claim 4.3** *Let  $A = [a, b]$  be a subterrain as above. Let  $u \neq b$  be any vertex in  $A$ . Then  $L(u)$  dominates  $u$  in that any vertex  $v$  to the right of  $u$  that is seen by  $u$  is also seen by  $L(u)$ .*

**Proof:** Let  $u'$  be the vertex immediately to the right of  $u$ . We show that  $u'$  cannot lie below the line  $l$  through  $L(u)$  and  $u$ , and therefore  $L(u)$  sees  $u'$ ; thus, we can apply the Order Claim to conclude that any vertex  $v$  to the right of  $u'$  that is seen by  $u$  is also seen by  $L(u)$ . Indeed, since  $L(u)$  is the leftmost vertex that sees  $u$ , all of the vertices to the left of  $L(u)$  lie below the line  $l$ , and, of course, none of the vertices between  $L(u)$  and  $u$  can lie above  $l$ . In particular, any vertex to the left of  $A$  that sees  $u'$  (and, by assumption, there exists such a vertex) cannot lie above  $l$ . This implies that  $u'$  cannot lie below  $l$ .  $\square$

We consider two subcases, according to whether or not the endpoints of  $A$  see each other.

**4.2.1 Case 1a: The end vertices of  $A$  see each other** Let  $A = [a, b]$  be a subterrain such that  $a$  and  $b$  see each other. For a vertex  $q \in A$ ,  $q \neq b$ , that is visible from  $b$ , we denote by  $A'_l(q)$  the vertices of  $A'$  that lie to the left of  $q$  and are not visible from  $b$  or  $L(q)$ . Similarly, let  $A'_r(q)$  denote the vertices of  $A'$  that lie to the right of  $q$  and are not visible from  $b$  or  $L(q)$ . If both  $A'_l(q)$  and  $A'_r(q)$  are nonempty, we say that  $q$  implies a *non-trivial division*.

**Claim 4.4** *If there exists a vertex  $q \in A$ ,  $q \neq b$ , such that,  $b$  sees  $q$ , and both  $A'_l(q)$  and  $A'_r(q)$  are nonempty (i.e.,  $q$  implies a non-trivial division), then  $A'_l(q)$  and  $A'_r(q)$  are guard independent.*

**Proof:** The vertices that can see one or more vertices of  $A'_l(q)$  can lie either to the right of  $L(q)$  and to the left of  $A$ , or in the subterrain  $[a, q]$ . This follows from the fact that both  $b$  and  $L(q)$  can see  $q$ . Similarly, the vertices that can see one or more vertices in  $A'_r(q)$  can lie either to the left of  $L(q)$  or in the subterrain  $(q, b)$ . Notice that  $q$  cannot see a vertex of  $A'_r(q)$ , since  $L(q)$  cannot see such a vertex and, according to Claim 4.3,  $L(q)$  dominates  $q$  with respect to the subterrain to the right of  $q$ .  $\square$

We say that  $A$  is in the *single-pocket case* if each vertex  $q \in A$  to the left of  $b$  that is visible from  $b$  implies a trivial division (either  $A'_l(q)$  is empty or  $A'_r(q)$  is empty).

**Claim 4.5** *Consider a subterrain  $A$  that is in the single-pocket case. Then there exists an (open) subterrain  $A^* = (c, d) \subset A$ ,  $d \neq b$ , such that,  $b$  cannot see any vertex in  $A^*$ , and all the vertices of  $A'$  that are not visible from  $b$ ,  $L(c)$ , and  $L(d)$  are in  $A^*$ .*

**Proof:** We may assume that there is no vertex  $q$  (to the left of  $b$  and visible from  $b$ ) for which *both*  $A'_l(q)$  and  $A'_r(q)$  are empty; otherwise, we could place guards at  $b$  and  $L(q)$  to see all of  $A'$ . Let  $c$  be the rightmost vertex (to the left of  $b$  and visible from  $b$ ) that implies a (trivial) division in which  $A'_l(q)$  is empty. Let  $d$  be the first vertex to the right of  $c$  that is visible from  $b$ . Then  $d$  implies a (trivial) division in which  $A'_r(q)$  is empty. Put  $A^* = (c, d)$ . By definition,  $b$  cannot see any vertex in  $A^*$ . Also, any vertex in  $A'$  that is not visible from  $b$ ,  $L(c)$ , or  $L(d)$  must lie in  $A^*$ , since, by definition,  $b$  and  $L(c)$  cover  $[a, c] \cap A'$  as well as  $c$ , and  $b$  and  $L(d)$  cover  $(d, b] \cap A'$  as well as  $d$ .  $\square$

**The single-pocket case.** Consider the single-pocket case, where  $A^* = (c, d)$  denotes the ‘‘pocket’’. Notice that (i) none of the vertices in  $(d, b]$  can see into the pocket  $A^*$ , and (ii) the vertices  $c$  and  $d$  see each other (since  $b$  sees both  $c$  and  $d$  but does not see any vertex in  $A^*$ ). Also we know that  $b$ ,  $L(c)$  and  $L(d)$  together cover  $A' - A^*$ .

For a subset of vertices  $S$ , we denote by  $V(S, p)$  the subset of vertices of  $S$  that are visible from a vertex  $p$ , and by  $V(S, P)$  the subset of vertices of  $S$  that are visible from at least one of the vertices of  $P$ .

**Lemma 4.6** *If  $V(A', L(d)) \cup V(A', d) \not\supseteq A' - A^*$ , then (i) one must place at least one guard outside of  $A^*$  in order to guard  $A' - A^*$ , and (ii) there exists a constant-size set of guards  $U$  that guards  $A' - A^*$ , and any other set of guards  $U'$  that guards  $A' - A^*$  includes a guard  $g'$  such that  $V(A' \cap A^*, U) \supseteq V(A' \cap A^*, g')$ .*

**Proof:** To prove the first part, we observe that  $L(d)$  dominates any vertex in  $A^*$  with respect to the subterrain to the right of  $d$  (applying the order claim to  $L(d)$  and  $d$ ), and  $d$  dominates any vertex in  $A^*$  with respect to the subterrain to the left of  $c$  (applying the order claim to  $d$  and  $c$ ). Now let  $v \in A' - A^*$  be a vertex that is not seen from  $L(d)$  or from  $d$  (such a vertex exists by our assumption). Clearly any guard that sees  $v$  cannot lie in  $A^*$ .

To prove the second part, put  $U = \{L(d), L(c), b\}$ . We already know that  $U$  guards  $A' - A^*$ . We now show that if  $g'$  is a guard that sees  $v$ , then  $V(A' \cap A^*, U) \supseteq V(A' \cap A^*, g')$ . If  $v$  is to the right of  $A^*$ , then in order to guard  $v$  one must locate a guard  $g'$  either to the left of  $L(d)$  or to the right of  $d$ . In both cases  $V(A' \cap A^*, g') = \emptyset$ . Else if  $v$  is to the left of  $A^*$ , then in order to guard  $v$  one must locate a guard  $g'$  either in  $[L(c), c]$  or to the right of  $d$ . In the former case it is possible that  $g'$  sees into  $A^*$ , but it is dominated by  $L(c)$ .  $\square$

The lemma above implies that if  $V(A', L(d)) \cup V(A', d) \not\supseteq A' - A^*$ , then we may place three guards at  $L(d)$ ,  $L(c)$ , and  $b$ , and charge these guards to the guard  $g'$  (in the proof above).

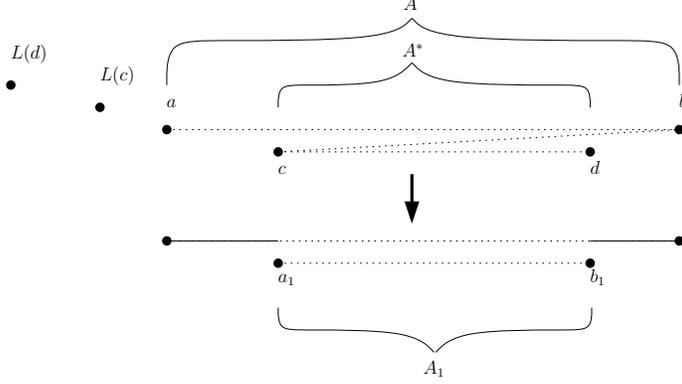

Figure 3: We can reduce the problem  $A$  to the Case 1a problem  $A_1 = [a_1, b_1] = [c, d]$ , since  $A' - A^* \subseteq V(A', L(d)) \cup V(A', d)$ .

We now consider the case where  $V(A', L(d)) \cup V(A', d) \supseteq A' - A^*$  (see Figure 3). In this case we say that  $A$  is *reducible*, and reduce  $A_0 = A$  to the Case 1a problem  $A_1 = [a_1, b_1] = [c, d]$ . Now, if  $A_1$  is also reducible, that is, if  $A_1$  is a single-pocket case with pocket  $A_1^* = (c_1, d_1)$ , and  $V(A', L(d_1)) \cup V(A', d_1) \supseteq A' - A_1^*$ , where  $A'$  is the *original*  $A'$ , then we reduce  $A_1$  to the Case 1a problem  $A_2 = [a_2, b_2] = [c_1, d_1]$ . This process continues until we reach a problem  $A_i = [a_i, b_i]$ ,  $i > 0$ , that is not reducible.

Notice that if we now place two guards at  $b_i$  and at  $L(b_i)$ , then all remaining unguarded vertices in  $A'$  would necessarily lie in the interior of  $A_i$ . This is because  $b_i = d_{i-1}$  and  $A_{i-1}$  was reducible. Thus we place these two guards and proceed as follows, according to the state that we entered. There are three possible such states:

- $A_i$  is not a single-pocket case, i.e., there is a vertex  $q \in A_i$  that implies a non-trivial division.
- $A_i$  is a single-pocket case, but  $V(A', L(d_i)) \cup V(A', d_i) \not\supseteq A' - A_i^*$ .
- $A_i$  has a constant-size solution.

In the first state, we divide  $A_i$  into two guard-independent subterrains (see Claim 4.4) as follows. Let  $q_l$  be the leftmost vertex in  $A_i$  that is seen from  $b_i$  and implies a non-trivial division. Let  $a'_i$  be the rightmost vertex to the left of  $q_l$  that is seen by  $b_i$ . Notice that  $q_l$  and  $a'_i$  see each other, since  $b_i$  sees both of them and does not see any vertex between them. Also notice that  $b_i$  and  $L(a'_i)$  together cover the subterrain  $[a_i, a'_i]$ , since  $a'_i$  implies a (left) trivial division. (Notice that it is impossible that  $a'_i$  implies a right trivial division, since, if it would, then so would  $q_l$ .)

Thus, in addition to the two guards that were already placed (i.e., at  $b_i$  and at  $L(b_i)$ ), we also place guards at  $L(q_l)$  and at  $L(a'_i)$ . We now solve the two guard-independent subterrains  $A_l = [a'_i, q_l]$  and  $A_r = (q_l, b_i]$  by applying to each of them the Case 1a algorithm. We charge the four guards that were placed to the increase by one of the lower bound due to the presence of a vertex that implies a non-trivial division.

In the second state we also place guards at  $L(d_i)$  and  $L(c_i)$  (in addition to the guards at  $b_i$  and  $L(b_i)$ ) according to Lemma 4.6 above, and solve the subproblem  $[c_i, d_i]$  by applying the Case 1a algorithm. We charge the four guards that were placed to the guard  $g'$  (see above). In the third state we simply solve the original problem with a constant number of guards.

All the above implies the following algorithm for Case 1a.

**Algorithm 4.7 (Case 1a)**

1. If there exist 2 (any constant number of) guards that together see all vertices in  $A'$  — done.
2. Let  $Q$  be the set of all vertices  $q \in A$  that imply a non-trivial division.

3. If  $Q \neq \emptyset$ , let  $q_l$  be the leftmost vertex in  $Q$ . Locate three guards at  $b$ ,  $L(q_l)$ , and  $L(a')$ , where  $a'$  is the rightmost vertex to the left of  $q_l$  that is visible from  $b$ . Solve each of the (guard-independent) subterrains  $A_l = [a', q_l]$  and  $A_r = (q_l, b]$  recursively using the Case 1a algorithm.
4. If  $Q = \emptyset$  (the single-pocket case)
  - (a) Compute the pocket  $A^* = (c_0, d_0)$ .
  - (b) If  $A = A_0$  is not reducible, place a guard at  $b$ . Otherwise, reduce until a subterrain  $A_i = [a_i, b_i]$  that is not reducible is reached and place guards at  $b_i$  and  $L(b_i)$ .
  - (c) If  $A_i$ ,  $i \geq 0$ , is a single-pocket case, then place guards at  $L(c_i)$  and  $L(d_i)$  and solve  $[c_i, d_i]$  recursively using the Case 1a algorithm.
  - (d) Else solve  $A_i$  recursively using the Case 1a algorithm.

**Lemma 4.8** *The Case 1a algorithm above computes a set of guards  $\mathcal{V}(A')$  for  $A'$ , whose size is bounded by some constant times the size of a minimum-cardinality such set of guards.*

We now turn to the general case, where  $A$ 's end vertices do not see each other.

**4.2.2 Case 1b: The end vertices of  $A$  do not see each other** We begin by computing the (upper) convex hull of  $A$ . Each of the edges of this convex hull corresponds to a subterrain whose endpoints see each other. Some of these subterrains may already be fully guarded (by  $\mathcal{G}$ ); we consider only those that are not yet fully guarded. Let  $A_1 = [a, b]$  be the leftmost subterrain that is not yet fully guarded, let  $A'_1$  be the subset of vertices in  $A_1$  that are not yet guarded, and let  $u$  be the leftmost vertex in  $A'_1$ . If there exists a single vertex to the left of  $A$  that sees all vertices in  $A'_1$ , then  $L(u)$  is necessarily such a vertex. Moreover, in this case, any vertex  $g$  (either to the left of  $A$  or in  $A$ ) that sees  $u$  is dominated by the pair of vertices  $L(u)$  and  $L(b)$ . Thus, in this case we can place guards at  $L(u)$  and at  $L(b)$  and charge this to the guard of the optimal solution that sees  $u$ .

Assume now that  $A'_1$  cannot be fully guarded by a single vertex to the left of  $A$ . In this case, we place a guard at  $L(b)$  and distinguish between two cases. If after placing a guard at  $L(b)$  there is no vertex to the right of  $b$  that remains to be guarded, then apply the Case 1a algorithm to subterrain  $A_1$ , and charge the guard at  $L(b)$  to the one time event of leaving Case 1b. If however there still remains an unguarded vertex to the right of  $b$ , then the two subterrains  $A_1$  and  $A_2 = A - A_1$  are guard independent. Indeed, any guard that can help guarding  $A'_1$  must lie in  $(L(b), b]$  and any guard that can help guarding  $A'_2$  must lie either in  $A_2$  or to the left of  $L(b)$ . Notice that  $b$  cannot help in guarding  $A'_2$ , since  $L(b)$  dominates  $b$  with respect to visibility to the right of  $b$ .

**Algorithm 4.9 (Case 1b)**

1. If all  $A$  is guarded — done.
2. Let  $A_1 = [a, b]$  be the leftmost subterrain that is not yet fully guarded, let  $A'_1$  be the subset of remaining unguarded vertices in  $A_1$ , and let  $u$  be the leftmost vertex in  $A'_1$ .
3. If there exists a single vertex to the left of  $A_1$  that sees all vertices in  $A'_1$ , then locate guards at  $L(u)$  and at  $L(b)$  goto #1.
4. Else locate a guard at  $L(b)$  and solve the two guard independent subproblems  $A_1$ , using the Case 1a algorithm, and  $A - A_1$ , using the Case 1b algorithm.

**Lemma 4.10** *The Case 1b algorithm above computes a set of guards  $\mathcal{V}(A')$  for  $A'$ , whose size is bounded by some constant times the size of a minimum-cardinality such set of guards.*

### 4.3 Case 2

Given a terrain  $T$ , let  $A = [a, b]$  be a subterrain that does not require a local guard, let  $A'$  be the subset of all vertices in  $A$  that are not yet guarded. In this case (Case 2), our goal is to compute a set of guards  $\mathcal{V}(A')$  for  $A'$ , where the guards in  $\mathcal{V}(A')$  may be located anywhere in  $T$ . We present a constant-factor approximation algorithm for computing a minimum-cardinality such set of guards.

We may assume that the endpoints of  $A$  are in  $A'$ , because otherwise we can simply replace  $A$  with the subterrain  $[a', b']$ , where  $a'$  (resp.  $b'$ ) is the leftmost (resp. rightmost) vertex in  $A'$ , and any (Case 2) solution to  $A$  is also a (Case 2) solution to  $[a', b']$  and vice versa. In particular we may assume that  $a$  and  $b$  are not vertices of the convex hull of the initial terrain (since  $A$  is contained in a subterrain defined by two consecutive vertices  $v_1, v_2$  of the convex hull of the initial terrain, and we already placed guards at these vertices).

**Observation 4.11** *For any vertex  $v \in A$ , the vertices  $L(v)$  and  $R(v)$  can see each other.*

(If there were a vertex  $v$  for which  $L(v)$  and  $R(v)$  cannot see each other, then the upper angle formed by  $L(v)$ ,  $v$ , and  $R(v)$  would be greater than  $\pi$ , and  $v$  would be a vertex of the convex hull of the original terrain (in between  $v_1$  and  $v_2$ ), contradicting our assumptions above.)

A vertex  $m \in A$  is called a *shared vertex* if  $m$  can be seen both from the left of  $A$  and from the right of  $A$ . For a shared vertex  $m$ , let  $A'_l(m)$  (resp.  $A'_r(m)$ ) denote the subset of vertices of  $A'$  that lie to the left (resp. to the right) of  $m$  and are not visible from  $L(m)$ ,  $m$ , or  $R(m)$ . As in Case 1a, we say that  $m$  implies a *non-trivial division* if both  $A'_l(m)$  and  $A'_r(m)$  are not empty.

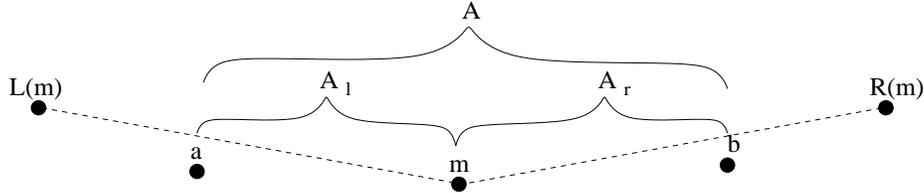

Figure 4: The two subterrains defined by a shared vertex that implies a non-trivial division are guard independent.

**Claim 4.12** *Let  $m$  be a shared vertex that implies a non-trivial division. Then the two subterrains  $A_l = [a, m)$  and  $A_r = (m, b]$  are guard independent.*

**Proof:** Any guard that can see a vertex in  $A'_l(m)$  must lie either between  $L(m)$  and  $m$ , or to the right of  $R(m)$ , while any guard that can see a vertex in  $A'_r(m)$  must lie either to the left of  $L(m)$ , or between  $m$  and  $R(m)$ . See Figure 4.  $\square$

**Claim 4.13** *There is at least one shared vertex in  $A = [a, b]$ .*

**Proof:**  $a$  is surely seen from the left of  $A$  (e.g., by the vertex immediately to its left), and  $b$  is surely seen from the right of  $A$ . Let  $c$  be the rightmost vertex in  $A$  that is seen from the left of  $A$ . (If  $c = b$ , then let  $c$  be the previous vertex in  $A$  that is seen from the left of  $A$ .) Let  $d$  be the vertex immediately to the right of  $c$ . Then  $d$  is necessarily seen from the right of  $A$ . We observe that either  $L(c)$  or  $R(d)$  must lie above the line through  $c$  and  $d$ . (Otherwise,  $c$  and  $d$  are vertices of the convex hull of the original terrain — impossible, see assumptions and observation above.) Therefore either  $c$  or  $d$  is a shared vertex. E.g., if  $L(c)$  lies above the line through  $c$  and  $d$  it must also see  $d$ , so  $d$  is a shared vertex in this case.  $\square$

Let  $M$  be the set of all shared vertices in  $A$ . According to the claim above  $M \neq \emptyset$ . We next show that any subterrain of  $A$  without shared vertices (i.e., vertices of  $M$ ) can be nicely divided into two subterrains. (The proofs are technical and omitted here; they appear in the full version available on the web.)

**Claim 4.14** *Let  $A^* = [l, r] \subset A$  be a subterrain such that  $A^* \cap M = \emptyset$ . Let  $u$  be a vertex in  $A^*$ . If  $u$  can be seen from the left of  $A$ , then any vertex in  $A^*$  to the right of  $u$  can also be seen from the left of  $A$  (and therefore cannot be seen from the right of  $A$ ).*

**Claim 4.15** *Assume that for each  $m \in M$ ,  $m$  implies a trivial division. Then, by placing a constant number of guards, one can reduce  $A$  either to a single instance of Case 1, or to two guard-independent instances of Case 1.*

**Algorithm 4.16 (Case 2)**

1. *If there exist 2 (any constant number of) guards that together see all vertices in  $A'$  — done.*
2. *Compute the set  $M$  of all shared vertices.*
3. *If there exists  $m \in M$  that implies a non-trivial division, then locate guards at  $L(m)$ ,  $m$ , and  $R(m)$  and solve (recursively) each of the two subproblems  $A_l$  and  $A_r$ .*
4. *Else, for each  $m \in M$  one of the sides is fully guarded by  $L(m)$ ,  $m$ , and  $R(m)$  and the other is not. Use Claim 4.15 in order to reduce  $A$  (by placing a constant number of guards) either to a single instance of Case 1, or to two guard-independent instances of Case 1. (Notice that if  $A$  is reduced to a single instance of Case 1, we charge the guards that were placed in doing so to the one time event of leaving Case 2.)*

**Lemma 4.17** *The Case 2 algorithm above computes a set of guards  $\mathcal{V}(A')$  for  $A'$ , whose size is bounded by some constant times the size of a minimum-cardinality such set of guards.*

## 5 Algorithm Analysis

Throughout our description of the algorithm, whenever guards were placed we gave an appropriate charging argument to justify why we could afford to place them. Consequently, we have shown that the size of the guarding set that is computed by the algorithm is bounded by a constant times the size of a minimum-size such set: we have obtained an  $O(1)$ -approximation, as desired. We have not attempted to minimize the constant factor; we leave it to the full paper to compute it exactly and to attempt to minimize it.

Concerning the running time of the algorithm, it is clear that it is polynomial. In the full draft of this paper (available online), we show that the running time is worst-case  $O(n^2)$ . The time bound comes from computing the visibility graph of the vertices; then, all subsequent work can be done within this time bound.

We have focused on the dominating set problem on terrains (DSPT), minimizing the number of vertex guards to guard all vertices. If we allow guards to be placed at *any* point on the terrain  $T$ , we obtain an  $O(1)$ -approximation algorithm by observing that any one guard  $g \in \overline{v_i v_{i+1}}$  on an edge of  $T$  can be replaced by two guards placed at the endpoints,  $\{v_i, v_{i+1}\}$ ; these two guards see at least as much as does  $g$ . If our goal is to cover *all* of  $T$ , rather than just the vertex set of  $T$  (i.e., the must-guard set is  $M = T$ ), then we can argue that by setting  $M$  equal to a polynomial-size ( $O(n^2)$ ) set of points on  $T$ , and applying our algorithm to select vertex guards that see all of  $M$  (using minor modifications in the algorithm to account for non-vertices that must be guarded), we obtain an  $O(1)$ -approximation to guard all of  $T$ . In summary, we have

**Theorem 5.1** *There exists a polynomial-time algorithm that yields an  $O(1)$ -approximation for terrain (or vertex) guarding by guards placed anywhere on the terrain (or only at vertices).*
